Reply to: Oliver J. Rosten (oliver.rosten@gmail.com)

Abstract

It is proposed to render the overloads of various algorithms accepting an execution policy usable in constant expressions. The goal is *not* for compile-time acceleration. Rather, it is to cleanly facilitate the use of algorithms built out of `std` components in runtime, runtime accelerated and compile-time contexts.

I. INTRODUCTION

Parallel algorithms, first appearing in C++17, are a powerful addition to the standard library. They facilitate runtime acceleration without clients having to pay attention to manual synchronization or other low-level implementation details. As such, they provide a natural, declarative abstraction which can offer significant performance gains.

In a seemingly orthogonal development, most `std` algorithms and their `ranges` counterparts have either been declared `constexpr` [P0202, P0896, P2562] or hopefully will be soon [P2283]. Given that the purpose of the parallel algorithms is to improve runtime behaviour, at first sight it makes little sense to add them to the `constexpr` club. However, algorithms naturally compose both with each other and other components. Allowing parallel algorithms to be used in constant expressions implies that composite algorithms can be straightforwardly implemented such that they can be used in compile time / runtime / runtime accelerated contexts, as desired.

Together with [P2283], which focuses on the specialized memory algorithms, these papers pave the way for all `std` / `ranges` algorithms to be usable in constant expressions, bringing an arc of language/library evolution to a satisfying conclusion. Note that, depending on their respective passage through standardization, it will likely fall to one or other of these papers to ensure that the

parallel overloads of the specialized memory algorithms are not overlooked.

Accepting the premise of this paper, the main design consideration is whether all current execution policies should be usable in constant expressions, or just `execution::seq`. This proposal errs towards the former, for reasons described below.

II. MOTIVATION & SCOPE

A. General Considerations

Suppose an author builds a function out of `std` algorithms (and potentially other components). Suppose further that they wish to use their function in both a compile time context and a runtime one, where the latter is amenable to acceleration. As things stand, this is possible but inelegant, requiring code duplication and a static branch. For example:

```
template<class Exec, class It>
constexpr void do_thing(Exec exec, It first, It last)
{
    if constexpr {
        std::sort(first, last);
        // More code
    }
    else {
        std::sort(exec, first, last);
        // More code
    }
}
```

A simple solution is to allow parallel algorithms to be usable in constant expressions, with a tacit understanding that, when so used, they almost certainly delegate to their serial counterparts.

However, is standardization really justified? There are a couple of concerns that need to be addressed. First, are there any domains for which runtime acceleration and compile time programming are both plausibly relevant? In my opinion, graphs provide a rich arena. On the one hand, it may be desirable to build a compile-time graph of, say, dependencies of a system. On the other, graphs are ubiquitous in runtime programming and can readily

reach sizes where acceleration of algorithms acting upon them is desirable. Furthermore, the proposed extension improves the regularity of the standard library and it is not unreasonable to suppose that this will be exploited.

Secondly, is it really true that parallel algorithms compose with each other? A reasonable objection may be that the end of each algorithm invocation represents a synchronization point. Therefore, successively invoking two parallel algorithms may not be optimal: it might be faster to arrange things such that there is a single call and hence only one synchronization point. However, on closer inspection this objection doesn't really hold water. It may be that the naïve composition is fast enough. It is not for us to guess at what the performance considerations might be or what profiling might reveal in some future application. The existing semantics are such that parallel algorithms can be stacked up, and there will be circumstances where it is appropriate to do so.

If the premise of allowing the parallel algorithms to be used in constant expressions is accepted, then there is a question as to the scope. There are two reasonable options as to precisely what is allowed in constant expressions: only `execution::seq` or all of the `execution` policies. There are various considerations.

B. Specific Options

1. The case for only `execution::seq`

1. Since constant evaluation of a parallel algorithm will almost certainly delegate to the standard version, there can be no misunderstanding as to what is happening. In particular, there will not be any potential confusion arising from clients expecting compile-time acceleration.
2. Switching from runtime evaluation to compile-time evaluation will (probably) give the same answer. This may not be true for other execution policies for certain algorithms were they to be allowed in constant expressions. For example, `std::reduce` states that the behaviour is non-deterministic if the relevant binary operator is not associative (or is not commutative). It is easy to cook up an example that demonstrates this, since floating-point arithmetic is not associative. Given an integer, N , consider the following view:

```
auto series = views::iota(1, N) |
    views::transform([](int i){ return 1.0f/i; });
```

Feeding this view to `reduce`, the various `execution` policies may lead to different answers. For MSVC, these differences appear for N at least as small as 255. By using a `constexpr` to force all evaluation to occur at compile time, the differences will disappear, meaning that some of the answers may change. Only allowing `execution::seq` in constant expressions will likely mean that the answer is

the same at runtime and compile time, at least on a given platform. However, strictly speaking this isn't actually guaranteed by the standard (see the critique below).

2. The case for all the `execution` policies

1. Demanding constant evaluation of existing code just works. There is no need to switch the execution policy to `execution::seq`.
2. Functions containing opaque usage of the `execution` policies may be directly rendered `constexpr`:¹

```
constexpr float sum(span<const float> s) {
    return reduce(par, s.begin(), s.end());
}
```

3. This approach does not unnecessarily constrain implementors:

`std::par` and friends merely relax requirements on the implementation, in hopes that implementations will do something useful with that freedom. Saying that I'm not allowed to give the implementation such freedom during constant evaluation doesn't make a lot of sense even if we all know that (typical, current) implementation will not do anything with it. —Davis Herring

C. Critique

It is marginal as to which choice is best. However, on balance the second is preferred, for the following reasons. First, ensuring compile-time/runtime consistency in this context is not compelling. Expecting a definitive answer from a non-deterministic algorithm is to misunderstand the algorithm. Indeed, even successive invocations may give different answers. This is the case for the `series` example above, using `reduce` with `par.unseq` on MSVC. Furthermore, there may anyway be differences across different library implementations, and the result that a particular implementation gives today could legitimately be different tomorrow if the internal details change. Secondly, of the remaining points, the one which stands out to me is the final one in favour of allowing all `execution` policies in constant expressions.

Therefore, this paper advocates option 2, above: allowing all `execution` policies to appear in constant expressions.

¹ Thanks to Davis Herring for pointing this out.

III. STATE OF THE ART

Both MSVC and libstdc++ have supported the parallel algorithms for some time. Sadly, libc++ is lagging behind. However, this in of itself does not seem like a strong reason for holding back on development in this area, particularly where this development is very much incremental.

In a somewhat similar vein, it is worth pointing out that the various parallel overloads are not available within `ranges`. This is a pity and will hopefully be rectified at some point. However, this proposal does not in any way interfere with that.

Finally, it is straightforward to adapt existing implementations for the purposes of this paper. See [6] for a selection of parallel algorithms, based on libstdc++, which are usable in constant expressions.

IV. IMPACT ON THE STANDARD

This is a pure library extension.

V. PROPOSED WORDING

The following proposed changes refer to the Working Paper [N4944]. With [P2562] just accepted into C++26, I have temporarily indicated changes proposed in that paper using blue. This will shortly be removed, once the Working Paper has been updated. Also, there is what looks to be an editorial issue which I will submit in due time: I believe that [mismatch] should be [alg.mismatch]. To ensure this is not forgotten about, I have temporarily indicated this as a wording change, below.

A. Modifications to “Header <algorithm> synopsis” [algorithm.syn]

```
// [alg.all.of], all of
template<class InputIterator, class Predicate>
constexpr bool all_of(InputIterator first, InputIterator last, Predicate pred);
template<class ExecutionPolicy, class ForwardIterator, class Predicate>
constexpr bool all_of(ExecutionPolicy&& exec, // see [algorithms.parallel.overloads]
                     ForwardIterator first, ForwardIterator last, Predicate pred);

...
// [alg.any.of], any of
template<class InputIterator, class Predicate>
constexpr bool any_of(InputIterator first, InputIterator last, Predicate pred);
template<class ExecutionPolicy, class ForwardIterator, class Predicate>
constexpr bool any_of(ExecutionPolicy&& exec, // see [algorithms.parallel.overloads]
                     ForwardIterator first, ForwardIterator last, Predicate pred);

...
// [alg.none.of], none of
template<class InputIterator, class Predicate>
constexpr bool none_of(InputIterator first, InputIterator last, Predicate pred);
template<class ExecutionPolicy, class ForwardIterator, class Predicate>
constexpr bool none_of(ExecutionPolicy&& exec, // see [algorithms.parallel.overloads]
                     ForwardIterator first, ForwardIterator last, Predicate pred);

...
```
